BACKGROUND

Controlling the lateral stability of movement is relevant for many types of transport vehicles and mobile platforms. Loss of lateral stability can manifest as skidding and overturning. In the theory of movement of transport vehicles, a distinction is made between partial and complete skidding. In the case of complete skidding, the chassis becomes uncontrollable. During lateral sliding, the chassis may encounter an obstacle (e.g., a curb in urban conditions), leading to a potential tip-over.

To prevent skidding, a stabilizing torque is created by redistributing traction forces between the driving wheels on each side. For light motor vehicles, this torque is implemented through a dynamic stabilization system (as discussed in [1, 2]). For platforms with individual electromechanical drives for each wheel unit, a similar effect can be achieved by redistributing torque between the traction electric engines.

When mathematically modeling overturning, two critical cases are considered: the onset of overturning and complete overturning. The former occurs when the normal reaction force under one side's wheels becomes zero. Complete overturning is when the center of gravity of the chassis passes through the critical line, for example, for a wheeled monohull vehicle. The line connects the contact points of the wheels on one side without losing contact with the ground. Once overturning begins, the vehicle becomes difficult to control along its trajectory, although reducing speed can sometimes prevent further development of the overturning.

Certain chassis types have specific design potentials to enhance stability. For example, a reconfigurable chassis with a planetary wheel propulsion system (PWP, as described in patent [3]) can increase lateral overturning stability by rotating the wheel blocks on one side (Fig. 1).

This stability margin allows for systematic movement along a slope with a specific angle of inclination.

$$\beta = \arctg(\Delta h / B^*).$$

The value of Δh depends on the distance between the axles of the wheels in the PWP wheel block. For a specific design, this angle can be estimated easily, but utilizing this feature requires additional strength calculations. The range of changes in the angle of inclination, in the absence of suspension, mainly depends on tire elasticity. In addition, the chassis must be reconfigured before moving along a slope, which is not always quickly achievable.

A related technical solution is described in [4], where the chassis can adapt to the geometry of the supporting surface to a limited extent by changing its configuration.

Modeling the loss of lateral stability for a reconfigurable chassis with PWP can consider the influence of external forces on lateral stability [5]. The action of these forces determines the critical speeds of movement and angles of transverse inclination of the supporting surface. For illustrative purposes, considering the industry-standard special cases of a mobile platform moving on a "pure slope" (i.e., moving across a slope) and on a "superelevation" is useful ([6–8]).

STUDY AIM

This work aims to substantiate the feasibility of using balancing mechanisms to increase the lateral stability of small-sized unmanned mobile platforms against overturning.

Problems to be solved:

- Provide a mathematical description of typical cases of losing lateral stability because of overturning and illustrate the influence of the balancing mechanism on chassis stability.
- Propose options for constructing balancing mechanisms to improve the lateral stability of small-sized unmanned vehicles and analyze their features at the circuit level.

MATERIALS AND METHODS

The approaches are based on the analysis of technical solutions in the field of creating platforms with extreme cross-country ability from companies such as "Letourneau" and "Lockheed" (USA) [3] and "Meile" (Switzerland), and on methods developed for creating planetary research vehicles at the Russian Research Institute of Transport Vechicles (VNITransmash, St. Petersburg). The study also uses methods based on the theory of ground vehicles.

RESULTS AND DISCUSSION

Lateral stability when turning on a slope

When modeling lateral stability on a slope, a most complex scenario is turning toward an uphill slope.

The following assumptions are made:

- Movement is uniform with a constant turning radius.
- The supporting surface has isotropic properties.
- The platform's center of gravity is at its geometric center.
- The wheels do not slip or skid.
- Tire elasticity and the influence of the spring suspension system are not considered.

The absence of a spring suspension system and the hypothesis about the symmetry of the side wheel blocks for a chassis with a PWP simplifies the design diagram (Fig. 2). No significant differences are observed from the case considered for a two-axle vehicle (as discussed in [6]).

In Fig. 2, the following designations C is center of gravity of the platform; B is the track width; h_c is the height of the center of gravity; β is the angle of transverse inclination of the supporting surface; G is the platform weight; $Z_{1,2}$ represents normal reactions under the wheels of the inner (lagging) and outer (advancing) sides; and Y is the total transverse reaction balancing the transverse force because of the action of inertia.

$$P_{jy} = MV^2/R.$$

In this equation, M is the mass of the platform, V is the speed of the center of mass, and R is the turning radius.

To estimate the critical values for the platform movement speed and the angle of inclination of the supporting surface for the onset of overturning, the following equation is used:

$$P_{jy} + G \left(\sin \beta - \frac{B}{2h_c} \cos \beta \right) = 0.$$

In particular, we solve for critical speed and inclination:

$$V = \sqrt{gR \left(\frac{B}{2h_c} \cos \beta - \sin \beta \right)}$$

and

$$\tan \beta = \frac{B}{2h_c} - \frac{V^2}{gR} \frac{1}{\cos \beta}.$$

The introduction of a balancing mass m creates a stabilizing moment proportional to its overhang arm y_m relative to point C :

$$T = mgy_m$$

and

$$V = \sqrt{gR \left(\frac{m}{M} \frac{y_m}{h_c} + \frac{B}{2h_c} \cos \beta - \sin \beta \right)}.$$

The critical speed at the onset of overturning increases nonlinearly with the stabilizing moment, enhanced by increasing the load mass ratio m/M and the ratio y_m/h_c . The greater the load mass and the lower the platform's center of gravity, the more effective the stabilizer.

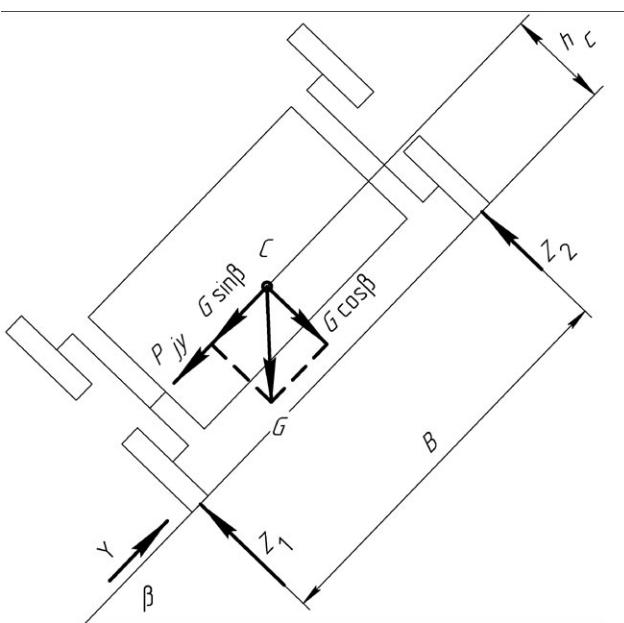

Fig. 2. The diagram for the analysis of roll stability in the case of turning on the inclination towards the bottom side.

Рис. 2. Расчетная схема для анализа устойчивости при повороте на косогоре в сторону спуска.

The stabilizing moment similarly influences the critical slope of the roadway. However, the evaluation equation becomes more complex:

$$\operatorname{tg}\beta = \frac{B}{2h_c} - \left(\frac{V^2}{gR} - \frac{m}{M} \frac{y_m}{h_c} \right) \frac{1}{\cos\beta}.$$

In practical problems, iterative methods should be used to solve such an equation.

For example, assuming $V=2$ m/s; $M=80$ kg; $m/M=0,2$; $B=0,4$ m; $y_m=0,75$ B; $h_c=0,195$ m, and $R=2$ B m, the critical angle for overturning increases by $\Delta\beta=6,3^\circ$ (approximately 25%).

Lateral stability when turning on a superelevation

When modeling the loss of stability during a turn on a superelevation, the same assumptions are made as for a turn on a slope. The forces acting on the platform are depicted in Fig. 3. Here, the center of rotation is located at point O, with the theoretical radius of rotation given by $R = |OC|$.

To estimate the critical values for the onset of overturning, such as the speed of movement and the angle of inclination of the supporting surface, we can derive the following equation under the accepted assumptions:

$$(P_{Jy} \cos\beta - G \sin\beta)h_c - (P_{Jy} \sin\beta + G \cos\beta) \frac{B}{2} = 0.$$

Hence, the parameters can be determined using the following equations:

$$V = \sqrt{Rg \frac{(2h_c \operatorname{tg}\beta + B)}{1 - B \operatorname{tg}\beta}},$$

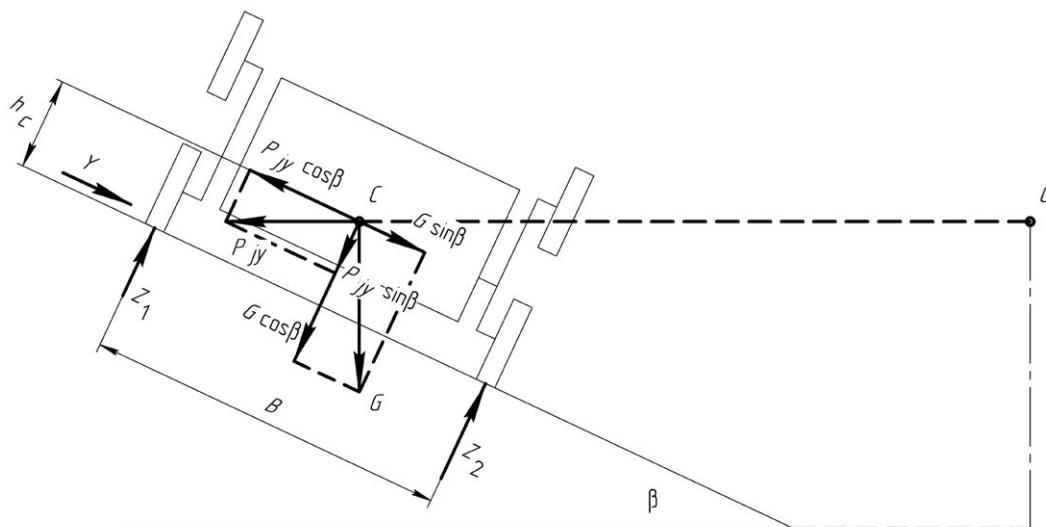

Fig. 3. The diagram for the analysis of roll stability in the case of cornering on inclined surface.

Рис. 3. Расчетная схема для анализа устойчивости при повороте на вираже.

$$\beta = \operatorname{arctg} \left(\frac{2V^2 h_c - gRB}{2gRh_c + V^2 B} \right).$$

Taking the stabilizer into account, the equation for the critical speed becomes

$$V = \sqrt{gR \frac{(2h_c \operatorname{tg}\beta + B) + 2y_m (1 + \operatorname{tg}^2\beta) m/M}{1 - B \operatorname{tg}\beta}}.$$

This equation applies for values of $\beta < 45^\circ$. For larger inclination angles, the design scheme must be adjusted. The change in the critical angle can be estimated by

$$\operatorname{tg}\beta = \frac{2gR \frac{m}{M} \frac{y_m}{\cos\beta} + (2V^2 h_c - gRB)}{2gRh_c + V^2 B}.$$

In practical applications this equation should be solved using iterative method. However, experience shows that chassis with a low center of gravity are less sensitive to loss of lateral stability because of overturning on a superelevation.

Principles of lateral stability control

Active lateral stability control can be achieved by creating a stabilizing moment using a certain weight. For small electric-powered platforms, an on-board energy storage device can serve as an effective counterweight because of its significant mass. Three main options are proposed:

- Pendulum stabilizer
- Rotating stabilizer
- Transverse linear stabilizer

Each method creates a stabilizing moment by altering the position of the on-board storage, which can complicate the design and reduce the efficiency of internal volume usage.

The pendulum stabilizer works similarly to the pendulum drive used on spherical robots [9], but design limitations make it less suitable for chassis with PWP. The rotating and transverse linear stabilizers are more practical, with the choice depending on the design features of the mobile platform and the tasks at hand.

Figure 4 presents the schematic options for a dual-mass (left) and single-mass (right) rotating stabilizer. The numbers indicate the vehicle body (1), weights (2), ball racer (3), and rotary base junction (4) (RBJ).

The design of the ball racer is similar to the solutions used to rotate the turret of a tank or the commander's

cupola of a military tracked vehicle. Examples of designs and calculation methods are given in [10]. Proven designs of the electromechanical drive for rotation and locking of the racer are also discussed there. The RBJ ensures the maintenance of electrical contact between the rotating part resting on the racer and the body of the mobile platform.

The dual-mass design allows for a smoother redistribution of the load between the sides and axles. This scheme is more complex and is advisable if a racer is installed on an unmanned platform to accommodate special equipment.

Figure 5 presents a simplified diagram of a stabilizer with transverse movement of the load, featuring single-mass (left) and dual-mass (right) configurations. The numbers indicate a vehicle body (1), weights (2), rack on the guide frame (3), and drive unit (4). Unlike

a stabilizer with a rotating mass, this design does not require an RBJ, significantly simplifying the unit and increasing reliability. Although this stabilizer does not allow controlling the redistribution of masses along the axes, it is simpler in design and more compact in the single-mass version.

For any of the considered designs, creating a closed-loop tracking control system with feedback on the roll angle of the mobile platform body and the position of the weight(s) is necessary.

Estimating performance and selecting drive parameters for moving the balancing mass represents a separate task and is not considered here.

However, the positioning accuracy for both options will be determined by the lateral clearance in the gear engagement of the drive, which primarily depends on the manufacturing accuracy of the gears. Additionally, when assessing speed the backlash in the gear engagement must be taken into account (e.g., [11, 12]).

CONCLUSIONS

1. For a lightweight unmanned mobile platform, a mechanism for lateral movement of the balancing mass can be recommended to ensure adaptive control of lateral stability.
2. An adaptive stability control system with rotational movement of two balancing masses will provide additional control of the longitudinal distribution of normal loads and can be necessary if the platform has a racer for special equipment.
3. The principles of stabilizing lateral stability considered can be applied to special small-sized mobile unmanned vehicles, regardless of the type of propulsion.

Further research in this direction involves constructing mathematical models to estimate the necessary kinematic, energy, and power parameters of the adaptive stabilization system of lateral stability as well as testing on a mock-up of a mobile platform.
