Access Site Complications by Intracardiac Interventions

Alexander V. Kimkov
St.-Katharinen Hospital GmbH Frechen, Germany

In recent decades, the number of intracardiac procedures using percutaneous puncture access has increased manifold. Despite the acquisition by operators of expertise and standardization of methods, the problem of complications remains relevant.

AIM: to analyze the frequency and nature of complications of percutaneous access in intracardiac interventions. Suggest recommendations to reduce the incidence of complications.

MATERIALS AND METHODS: analysis of data published in international peer-reviewed journals on the topic, as well as the experience of the vascular surgery clinic of St. Katarina’s Hospital.

CONCLUSIONS: the frequency and severity of complications depend on the experience of the operator, the size and frequency of changing the instrument, as well as compliance with the rules of preoperative diagnosis and postoperative management of the patient.

RECOMMENDATIONS: standardized preoperative preparation, careful planning of the intervention, analysis of the state of the access vessels, compliance with the rules of vessel puncture and competent performance of postoperative compression in combination with the use of suturing devices according to indications can reduce the frequency and severity of complications.

Keywords: vascular surgery; arrhythmology; access complications; kardiology.

**Осложнение места доступа при интракардиальных вмешательствах**

**А.В. Кимков**

Госпиталь св. Катарины, Кёльн-Фрехен, ФРГ

В последние десятилетия многократно возросло количество интракардиальных процедур с использованием чрезкожного пункционного доступа. Несмотря на приобретение операторами экспертизы и стандартизации методов, проблема осложнений остаётся актуальной.

**Цель:** проанализировать частоту и характер осложнений чрезкожного доступа при интракардиальных вмешательствах. Предложить рекомендации для снижения частоты осложнений.

**Материалы и методы:** анализ данных, опубликованных в международных рецензируемых журналах по теме, а также опыта клиники сосудистой хирургии госпиталя св. Катарины.

**Выводы:** частота и тяжесть осложнений зависят от опыта оператора, размера и частоты смены инструмента, а также соблюдения правил предоперационной диагностики и послеоперационного ведения пациента.

**Рекомендации:** стандартизированная предоперационная подготовка, тщательное планирование вмешательства, анализ состояния сосудов доступа, соблюдение правил пункции сосуда и грамотное выполнение послеоперационной компрессии в сочетании с применением ушающих устройств по показаниям может снизить частоту и тяжесть осложнений.

**Ключевые слова:** сосудистая хирургия; аритмология; осложнение доступа; кардиология.

In 1929, the German urologist W. Forsmann inserted a urinary catheter into his cubital vein and pushed it in a central direction, and then took a radiographic image of his chest in a frontal view. This event was the first proven case of cardiac catheterization [1]. Subsequently, in 1956, he was awarded the Nobel Prize in Medicine. In 1953, the Swedish radiologist Seldinger proposed a vessel puncture technique for subsequent manipulations, named after him [2]. Finally, in the 1990s, Kiemenje and Laarman developed and implemented in clinical practice the technology of transradial percutaneous coronary intervention [3]. Currently, interventional technologies are the basis of many specialties.

In 2018, 220,000 coronary stenting interventions were performed in the Russian Federation, with approximately a 4-fold increase over 10 years. In the USA, 75,000 atrial ablations were performed in 2017 [4]. In all cases, manipulations were performed either through transradial or transfemoral access. Discussions about the advantages of one approach over the other ended after the publication of several studies, especially the RIVAL study [5]. At present, the radial approach is preferred in case of a suitable anatomy and in the absence of specific contraindications.

Despite the vast experience gained, complications of the access site during interventional procedures remain a major problem. In the 1990s, complications occurred in 6% of all patients after coronary interventions; 22%–25% of these cases required blood transfusion, and 21%–38% required surgery [6, 7]. Currently, with the accumulation of experience, the incidence of complications has significantly decreased (up to 1%–2%) [8–11], although it is still a concern given the huge number of interventions. Therefore, the mortality rate in patients who survived such a complication is 7.5% (1.1% without complications), the duration of hospital stay is twice longer, and the cost of inpatient treatment is almost two times higher ($9,583 vs. $18,350) [12].

The main complications of the access site are hematoma, ischemia of the access site in the limb dependent on the vessel, hemorrhage (including hemodynamically significant), false aneurysm requiring revision, vessel evulsion, and infection. Socioeconomic and psychological problems (staff distraction, psychological trauma to the patient, blocking the patient, and excessive use of resources) should also not be ignored. Factors that increase the risk of complications include female gender, age of 65 and older, body surface area greater than 1.62 m², long duration of the procedure, high puncture site with transfemoral access, history of hemorrhagic diathesis, obesity, uncontrolled arterial hypertension, renal failure (creatinine level > 2 mg/d), use of glycoprotein IIb/IIIa inhibitors, and peripheral atherosclerosis [8–14].

Complications of the radial access

Occlusion of the radial artery is the most common complication with appropriate access. It occurs in 2%–18% of all transradial interventions14, 15, and its occurrence depends largely on the surgeon’s experience, the method of compression and, most importantly, the quality of its application. According to studies, the course of this complication is usually asymptomatic, requiring no special treatment. The pathogenetic process is based on thrombogenesis in areas of the affected intima. Occlusion of the radial artery becomes symptomatic only in case of palmar anastomoses failure or in the presence of ulnar artery occlusion. In this situation, conducting an Allen test before the study will help prevent the development of a serious complication. This test is technically simple and does not require additional resources. In case of occlusion in both arteries, the patient is threatened with a higher risk of ischemia in the region dependent on these vessels and, in case of an unfavorable course, the development of necrosis and the need for amputation. In addition, perioperative injection of 5,000 IU heparin reduces the risk of vessel occlusion (71% vs. 4.3%). Factors that increase the risk of radial artery occlusion include excessive postoperative compression, repeated punctures, and large sluice diameters.

Non-occlusive lesions of the radial artery. This group includes, first, intimal hyperplasia and vascular remodeling. Studies of postoperative intima using intravascular ultrasound scan showed significant intimal hyperplasia with a resulting significant reduction in the diameter of the latter. A small series using optical coherence tomography revealed intimal tears in a significant group of patients (67%) and media dissection (36%). This damage leads to a decrease in the quality of the vessel during its subsequent use as a graft in arterial myocardial revascularization. A retrospective series revealed a decrease in the early patency of such grafts.

Spasm of the radial artery occurs in 5%–10% of all interventions. It rarely leads to serious consequences; however, it can lead to the failure of the procedure. Risk factors include small vessel diameter, female gender, multiple catheter replacements, use of a long sluice, and lack of experience of the operating surgeon. The radial artery has a well-defined tunica media, which is under the control of α-1 adrenoceptors. For prophylactic purposes, sedation of the patient and local anesthesia can be used to control the effect of circulating endogenous catecholamines. Spasms respond well to treatment. Currently, nitroglycerin, subcutaneous injections of lidocaine, and various vasodilatory cocktails are used. The use of low-profile hydrophilic sluices also contributes to a reduction in the risk of spasm [25, 26]. Ouadhour et al. suggested based on their own research that subcutaneous administration of 0.5 mg isosorbide dinitrate with 1% lidocaine for local anesthesia can improve the radial access function [27].

Vessel perforation is a rare complication, which can lead to serious consequences in the form of loss of access, the need for conversion and, in case of an untimely response, the development of hematoma, compartment syndrome, and ischemia of the dependent area. In an analysis by Calvino-Santos et al., its incidence of less than 1% of cases was reported. Data from a large series showed an incidence of < 0.1% [6]. Moreover, most of these complications occurred in short women with tortuous
vessels of the forearm [30]. Access safety in these patients can be improved by using a long sluice [30] and a guiding catheter [31]. If perforation is detected early, a small-diameter peripheral balloon can be used for angioplasty [32].

Compartment syndrome is a much rare but hazardous complication that requires emergency fasciotomy. Its incidence has been described in large series of cases at 0.004% [33]. The diagnosis is established based on clinical manifestations in the form of a massive tumor of the forearm with symptoms of peripheral ischemia, primarily neurological disorders.

False aneurysm is another rare complication. It occurs in < 0.1% of cases [6] and manifests itself as a penetrating injury to the vessel, which was not recognized in due time. The false aneurysm course is also facilitated by multiple punctures of the vessel and incorrect application of compression of the access site (for example, TR-Band) after the end of the procedure. Diagnosis is made by ultrasound. Conservative (adequate compression, injection of thrombin into the false aneurysm cavity under ultrasound control [34, 35]) or surgical (revision of the access site with hematoma evacuation and suturing) treatment is performed. Ligature of the radial artery is rarely required.

Table 1 presents the most common complications of radial access, their incidence, and methods of prevention and treatment.

### Complications of the transfemoral access

Despite the proven advantages of the transradial approach, the transfemoral approach continues to be widely used when indicated or preferred by a particular operating surgeon. The most common complications of this approach are puncture site hematoma, retroperitoneal hematoma, false aneurysm, arteriovenous fistula, and arterial dissection restricting the blood flow. Less complications are infections, thrombosis, and long-term lesions of nerve structures. Incorrect puncture of the vessel plays a huge role in the occurrence of these complications. Many interventional specialists do not have practical surgical experience and often deviate from the recommended puncture technique, considering it an insignificant stage of the intervention.

In addition, the anatomy of the common femoral artery is characterized by low variability expressed in different bifurcation heights. Ultrasound-guided puncture is generally recommended. When performing a puncture under radiological control, a specialist should focus on the femoral head and puncture slightly mediially to its center toward the xiphoid process at an angle of 45°. The anatomy of the common femoral artery is schematically presented in Figure 1.

Puncture should not be performed above the inguinal ligament, since in this area, the external iliac artery is oriented in the anteroposterior direction, and the puncture cannula passes parallel to the vessel without providing a puncture. In addition, in case of a high puncture, there is no bone base for performing postoperative compression. In this regard, the risk of bleeding with the formation of a retroperitoneal hematoma increases significantly.

The following factors should be considered risk factors for complications:
- insufficient knowledge of the femoral artery anatomy;
- little experience of the operating surgeon;

Hematoma of the puncture site is the most common complication, and it has been reported to occur in 5%–23% of cases by different authors. The hematoma scope varies from slight staining of the skin at the puncture site to a massive tumor requiring surgical treatment and blood transfusion. First, the causes of hematoma include multiple puncture attempts, incorrect or insufficiently long-lasting postoperative compression, and incorrect use of suturing devices. In the vast majority of cases, hematomas do not require special treatment and persist for 1–2 weeks. Follow-up and local therapy with heparin ointment are usually sufficient. If a growing hematoma is detected during the intervention itself, it is possible to use endovascular methods of treatment, such as balloon compression or implantation of a short stent or stent prosthesis. In this case, a contralateral approach is required. If it becomes necessary to implant a stent or a stent graft, it should be taken into account that the puncture site is anterior to the hip joint, that is, it is located in the mobile segment. The implantation of a stent in such a segment poses the risk of implant fracture and, as a consequence, the occurrence of vascular obstruction, limiting blood flow. Sometimes surgical treatment is necessary due to the hematoma size. The CT presentation of such a hematoma is shown in Figure 2. In case of the rapid development of a massive hematoma, necrotic changes in soft tissues are also possible. An example of such a case is presented in Figure 3. A special variant of local hematoma leads to the occurrence of a false aneurysm (0.5%–9%), and emergency surgery is indicated in this case. When performing postoperative compression, the size of the tool used to catheterize the vessel should be considered. The compression force should be approximately 20 mmHg above the systemic systolic pressure. The reference points in Table 2 can be used to determine the compression time.

Cardiac Arrhythmias Vol 2, № 1, 2022

When using tools larger than 6 Fr in diameter for arterial access, the use of a suturing device is recommended. In the early postoperative period, strict adherence to bed rest by the patient and control of the puncture site by the department staff are of key importance.

Retroperitoneal hematoma is a rare but serious complication. It has an incidence of 0.8%–0.44%. The occurrence of this pathology is associated primarily with suprainguinal puncture of the external iliac artery. The main danger consists in the delayed manifestation of symptoms, namely hypovolemia, pain in the ipsilateral hypogastrium, and deterioration in the general condition of the patient. Diagnosis is based on physical examination, ultrasound scan, and CT scan with contrast agent. Treatment includes an emergency revision with imposition of a vascular suture, hematoma evacuation, and drainage in the retroperitoneal space. In some cases, interpose implantation and blood transfusion are required. Rebleeding or lymphocele occurs in rare cases (Figure 4).

Arteriovenous fistula (0.2%–2.1%) occurs when an artery is accidentally punctured through a vein or when a vein is accidentally punctured through an artery (Figure 5). In most cases, such fistulas close spontaneously within a few weeks.

Surgical treatment is indicated in case of signs of overload of the heart compartments.

To take home
- Before puncturing the radial artery, the Allen test should be performed;
- Control the tool position in the vessel lumen;
- Avoid frequent, unnecessary tool changes;
- Perform adequate hemostasis;
- When using suturing devices, follow the instructions for use;
- Perform manual compression properly;
- Encourage patients to stay in bed;
- Control the access site before discharge;
- Share the experience.
